Abstract

We investigated the effect of the environment on the electrical conductance of a single benzene-1,4-diamine (BDA) molecule bridging Au electrodes, using the scanning tunneling microscope (STM). The conductance of the single BDA molecule junction decreased upon a change in the environment from tetraglyme, to mesitylene, to water, and finally to N₂ gas, while the spread in the conductance value increased. The order of the conductance values of the single BDA molecule junction was explained by the strength of the interaction between the solvent molecules and the Au electrodes. The order of the spread in the conductance values was explained by the diversity in the coverage of the BDA molecule at metal electrodes and atomic and molecular motion of the single-molecule junction.

Introduction

The electron transport properties through a single molecule bridging metal electrodes (single-molecule junction) have attracted much attention toward the realization of molecular scale electronics [1,2]. Electrical conductance of the single-molecule junction was investigated by means of mechanically controllable break junction (MCBJ), scanning tunneling microscope (STM), and other techniques. In the simple tunneling model, the transmission \( T(E) \) of the single-molecule junction can be represented by

\[
T(E) = \sum_k \frac{(2\pi^2 pC_{rk}C_{sk}^*)^2}{(E-e_k)^2 + \eta_k^2} \tag{1}
\]
where $t$, $\rho$, $C_{rk}$ and $\epsilon_k$ are the hopping integral between the metal and molecular orbitals (MO), the local density of states (LDOS) of the metals at the Fermi level ($E_F$), the $k$th MO coefficient at site $r$, and the $k$th MO energy, respectively. The infinitesimal $\eta_k$ is determined by Green’s function and DOS [3]. The conductance of the single molecule junction depends on the parameters of $t$, $\rho$, $C_{rk}$, $\epsilon_k$, and $\eta_k$.

While advances have been made in the understanding of the conductance of single-molecule junctions based on intrinsic factors [4,5], uncertainties still remain, and the effects of the environment on the conductance of the single-molecule junction are still unclear. In solution, solvent molecules can interact with the molecule bridging the metal electrodes, and/or with the metal electrodes themselves. Wu et al. demonstrated that the aromatic $\pi-\pi$ coupling between adjacent molecules affected the formation of the molecule junction and electron transport through the molecule junction [6]. Venkataraman’s group and our group independently evaluated the electron-transport properties of $\pi$-stacked systems [7,8]. We showed that the conductance of the $\pi$-stacked system decreased with the number of $\pi$ molecules, and the decrease in conductance per unit of electron-transport distance was comparable to that of the conventional single-molecule junction. Dahlke et al. investigated the effect of the surrounding molecules on the single phenylene diisocyanide molecule junction, by means of theoretical calculations [9]. The electronic structure and conductance of the phenylene diisocyanide molecule were affected by surrounding phenylene diisocyanide molecules when the distance between the molecules was less than 0.6 nm. Tawara et al. investigated the spread in conductance values of the single benzenedithiol molecule junction in water [10]. They showed that water molecules affected the dynamics, and more specifically, the $C-S$ stretching mode of the single-molecule junction. The conductance of the single benzenedithiol molecule junction depended on the length of the $C-S$ bond; thus, the spread in the conductance value was suppressed in water compared with that in vacuum. These experimental and theoretical studies suggested that the solvent molecule could affect the electron-transport properties of the single-molecule junction. In the present study, we investigated the effect of the environment on the electron-transport properties of the single benzene-1,4-diamine (BDA) molecule junction in water, tetruglyme, and mesitylene, with each medium having different viscosity and dipole moment.

**Experimental**

The single-molecule junctions were fabricated in an electrochemical cell mounted in a chamber, which was filled with high-purity N$_2$ gas (purity $>99.999\%$) in order to avoid any effects of oxygen and water in the air. The conductance measurements were performed by using electrochemical STM (Pico-SPM, Molecular Imaging Co.) and a Nano Scope IIIa controller (Digital Instruments Co.), where the STM tip was made from a Au wire (diameter $\sim0.25$ mm, purity $>99\%$). Figure 1 shows the schematic view of the experimental setup. For the conductance measurement in water, the Au tip was
coated with wax to eliminate ionic conduction. The substrate was Au (111), prepared by a flame-annealing and quenching method. For the measurements in liquid, a solution of BDA (10 mM) in water, tetraethylene glycol dimethyl ether (tetraglyme), or mesitylene was fed into the electrochemical cell. The Au tip was repeatedly moved in and out of contact with the Au(111) substrate at a rate of 100 nm/s. Conductance was measured during breaking of the Au contact, and was not dependent on the breaking speed below 100 nm/s. The bias voltage between the tip and substrate was 20 mV. The experiments were performed on three independent samples for each solution. For comparison, the conductance measurement was also performed without solution. A self-assembled monolayer (SAM) of BDA on the Au substrate was prepared by exposing the substrate to methanol solution containing 10 mM BDA overnight. The conductance measurements were performed in N₂ gas.

Results

Figure 2 shows the typical conductance traces of Au contacts in tetraglyme solution containing 10 mM BDA (green curves). The conductance changed stepwise, with a step height corresponding to the quantum unit, \( G_0 \) (\( G_0 = 2e^2/h \)). The conductance histogram constructed from 2200 conductance traces (Figure 3) shows peaks at 1 \( G_0 \) and 2 \( G_0 \). The conductance of a metal nanocontact is represented by \( G = G_0 \sum T_i \) where \( T_i \) is the transmission probability of the \( i \)th conductance channel [2]. In the case of a Au nanocontact, the single Au 6s channel with transmission of 1 is the contributor to the electron transport. The 1 \( G_0 \) plateau in the conductance trace and the 1 \( G_0 \) peak in the conductance histogram correspond to the Au atomic contact. The clean Au atomic contact was formed in tetraglyme. A clear 1 \( G_0 \) plateau in the conductance trace and 1 \( G_0 \) peaks in the conductance histograms were also observed in other environments, as shown in Figure 2 and Figure 3. The formation of the Au atomic contact and conductance of the Au atomic contact were not affected by the change of environment.

Figure 4 shows the conductance traces of Au contacts in tetraglyme containing 10 mM BDA, in the low conductance regime (green curves). The trace shows a plateau around 0.01 \( G_0 \). The conductance histogram (Figure 5) constructed from 3300 conductance traces also shows a peak around 0.01 \( G_0 \). There were no steps in the conductance traces, and no...
features in the conductance histogram below 0.01 \( G_0 \). However, under the \( \text{N}_2 \) atmosphere few conductance traces showed steps below 0.01 \( G_0 \), leading to the appearance of a weak feature below 0.01 \( G_0 \). In the absence of BDA, neither steps nor peaks were observed in the same conductance regime. These experimental results indicate that the 0.01 \( G_0 \) plateau in the trace and 0.01 \( G_0 \) in the conductance histogram correspond to the single BDA molecule junction [4-7]. The conductance of the single BDA molecule junction was determined to be 0.010 ± 0.0014 \( G_0 \) in tetraglyme based on statistical analysis of the repeated measurements (see Supporting Information File 1 for details).

\[
\sigma = 0.26, 0.18, 0.16, \text{ and } 0.14 \text{ in } \text{N}_2 \text{ gas, water, mesitylene, and tetraglyme, respectively. The spread in the conductance value decreased in the order of } \text{N}_2 \text{ gas, water, mesitylene, and tetraglyme.}
\]

**Discussion**

Here, we discuss the effect of the environment on the conductance of the single BDA molecule junction. In the single BDA molecule junction, electron transport is mediated by the highest occupied molecular orbital (HOMO) of BDA [12]. The conductance of a single BDA molecule junction increases for decreasing energy difference (\( \Delta E \)) between the HOMO and the Fermi level \( (E_F) \) of Au (Equation 1). When the BDA molecule adsorbs on the Au electrode, the value of \( E_F \) increases. This is due to charge transfer from the BDA molecule to Au. In the presence of the solvent, the solvent molecule can adsorb on the Au surface by replacing the surface-bound BDA molecules. The amount of charge transfer between the solvent molecule and Au is smaller than that between the BDA molecule and Au. This is due to the relative weakness of the interaction. The value of \( E_F \) decreases through replacement of the BDA molecules with the solvent molecules. The replacement reaction decreases \( \Delta E \), and thus, the conductance of the single BDA molecule junction increases when solvent molecules adsorb on the Au surface. The replacement reaction frequently occurs in the solvent, which strongly interacts with Au (although not as strongly as the BDA molecules).

In the case of physical adsorption, the strength of the molecule–metal interaction increases with the molecule size. The molecule sizes of water and mesitylene are 0.3 nm and 0.8 nm, respectively. By considering the molecule size and other physical properties (e.g., dipole moment), the interaction between the Au electrode and solvent would decrease in the order of tetraglyme, mesitylene and water. Therefore, the conductance of the single BDA molecule junction in tetraglyme, mesitylene, water and \( \text{N}_2 \) gas decreased in that order.

The spread in the conductance value of the single BDA molecule junction in \( \text{N}_2 \) gas, water, mesitylene, and tetraglyme decreased in that order. We discuss the effect of the environment on the spread in the conductance value by considering the atomic and molecular motion of the single-molecule junction and molecular adsorption at the metal electrodes. First, the atomic and molecular motion of the single molecule junction was suppressed in the following order: \( \text{N}_2 \) gas, water, mesitylene, and tetraglyme. This was done in order to reflect the molecular weight and viscosity of the solvent; the conductance of the single-molecule junction depends on the atomic structure of the
junction. When the atomic and molecular motion of the single-molecule junction is suppressed, the conductance of the single-molecule junction does not significantly change with time, leading to a decrease in the spread of the conductance value. Therefore, the spread in conductance value decreased with the change in environment in the following order: N₂ gas, water, mesitylene, and tetraglyme. Second, the coverage of BDA molecules on a Au electrode decreased in the following order: in N₂ gas, water, mesitylene, and tetraglyme. This order reflects the strength of the interaction between the Au electrode and the solvent, as discussed in the previous section. The amount of the charge transfer from the BDA molecule to Au (decrease in conductance value) was largest for the single BDA molecule junction under N₂ atmosphere, compared to the single BDA molecule bridging clean Au electrodes. The spread in the conductance value of the single-molecule junction increased with the change in the conductance value relative to that of the single BDA molecule bridging the clean Au electrodes. Therefore, the spread in conductance value decreased with changing environment in the order of N₂ gas, water, mesitylene, and tetraglyme.

Conclusion
The electrical conductance of the single BDA molecule bridging Au electrodes was investigated in tetraglyme, mesitylene, water and N₂ atmosphere. The conductance of the single BDA molecule junction in tetraglyme, mesitylene, water, and N₂ decreased in that particular order. The energy difference between £F and the HOMO of BDA decreased when the surface-bound BDA molecules were replaced by solvent molecules. Therefore, the conductance of the single BDA molecule junction showed higher conductance values in tetraglyme, which interacted relatively strongly with the Au electrodes. On the other hand, the spread in conductance value of the single BDA molecule junction in N₂ gas, water, mesitylene, and tetraglyme decreased in that order. The atomic and molecular motion of the single-molecule junction is suppressed by the solvent. In the organic solution, the spread in conductance value was smaller compared to the results in N₂, because the atomic and molecular motion of the single-molecule junction was suppressed. The spread in the conductance values can be also explained by the diversity of the coverage of the BDA molecules on the Au electrodes.
