Photocatalytic Appel reaction enabled by copper-based complexes in continuous flow

Clémentine Minozzi, Jean-Christophe Grenier-Petel, Shawn Parisien-Collette and Shawn K. Collins*

Abstract
A copper-based photocatalyst, Cu(tmp)(BINAP)BF₄, was found to be active in a photoredox Appel-type conversion of alcohols to bromides. The catalyst was identified from a screening of 50 complexes and promoted the transformation of primary and secondary alcohols to their corresponding bromides and carboxylic acids to their anhydrides. The protocol was also amendable and optimized under continuous flow conditions.

Introduction
Synthetic photochemistry and photocatalysis continues to influence molecular synthesis [1-4]. In exploring photochemical reactivity manifolds, there exists the potential to discover new methods to construct important molecular fragments, as well as revamp traditional chemical transformations. One such process is the Appel reaction [5], which employs PPh₃ and an electrophilic halogen source to promote the formation of an organic halide from the corresponding alcohol (Figure 1) [6,7]. The Appel reaction is representative of a host of transformations that require stoichiometric reagents to effect a functional group change of an alcohol. In 2011, Stephenson and co-workers reported that photocatalysis could be used to promote the alcohol→halide conversion using low catalyst loadings of a ruthenium-based catalyst (Ru(bpy)₃Cl₂, 1 mol %) in the absence of PPh₃ as a reductant (Figure 1) [8]. The method possesses numerous advantages (wide functional group tolerance, no formation of oxidized phosphine byproducts [9-14], mild reaction conditions and visible-light irradiation), which should be easily embraced by the synthetic community. To further develop the photochemical alcohol→halide transformation, the use of alternative photocatalysts based upon more abundant metals was envisioned [15-18]. Specifically, our group has demon-
Strated that heteroleptic Cu(I) complexes [19-21] have significant potential as photocatalysts that can promote a variety of mechanistically distinct photochemical transformations including single electron transfer (SET), energy transfer (ET), and proton-coupled electron transfer (PCET) reactions [22-26]. Herein, the evaluation of Cu(I)-complexes for photocatalytic Appel reactions and demonstration in continuous flow is described.

**Results and Discussion**

The first step in identifying a heteroleptic diamine/bisphosphine Cu(I)-based photocatalyst for the conversion of an alcohol to bromide involved screening a wide variety of structurally varied complexes. Our group has previously demonstrated that the nature of each ligand influences the physical and photophysical properties as well as catalytic activity of the resulting catalyst (Figure 2) [27].

A library of 50 different catalysts was evaluated in the conversion of alcohol 1 to bromide 2 (Figure 2 and Figure 3). Several homoletic complexes were not evaluated due to problematic...
oxidation or low solubility. Reactions were irradiated at either 394 nm (purple LEDs) or 450 nm (blue LEDs), depending on the UV–vis absorption characteristics of the photocatalysts [28]. Stephenson and co-workers had previously reported that a primary alcohol structurally similar to 1 underwent conversion to the corresponding bromide in 96% yield upon irradiation in the presence of Ru(bpy)$_3$Cl$_2$ (1 mol %). The screening for a suitable copper-based catalyst was performed under identical reaction conditions whereby the Ru-based photocatalyst was substituted for the Cu-based complex. Control reactions performed in the absence of light or in the absence of catalyst at either 394 or 450 nm revealed no conversion to the bromide. From the results, none of the homoleptic complexes promoted the alcohol-to-halide conversion (1→2, see the light blue entries in the front row of Figure 3). While many of the heteroleptic complexes promoted the reaction, some trends were apparent. In general, amongst the phosphines the dppf-based complexes were poor catalysts, while when considering the diamine ligands the dq and bathophenthroline catalysts provided poor to modest yields. Also, BINAP and Xantphos-based catalysts tended to afford higher yields of 2, while amongst the diamines, the triazole-based complexes were almost all efficient at providing 2 (54–87% yield, not including dppf-based complexes). Interestingly, the best catalyst for the transformation (Cu(tmp)(BINAP)BF$_4$, 99% of 2) was a poor catalyst for a previously reported photoredox reaction [27]. It should be noted that Cu(tmp)(BINAP)$^+$ possesses an excited state reduction potential of −1.93 V vs. SCE, much greater than that of Ru(bpy)$_3$Cl$_2^+$ (−0.81 V vs SCE), albeit the copper complex has a much shorter excited state lifetime (≈4 ns vs ≈1100 ns for Ru(bpy)$_3$Cl$_2^+$). The excited state reduction potential should match favorably with CBr$_4$ ($\frac{1}{2} E = 0.30$ V vs SCE) in DMF [29]. Note that many of the corresponding homoleptic copper-based sensitizers were ineffective at promoting the Appel-type reaction.

With conditions in hand for the formation of the bromides, different alcohols were converted to their corresponding halides.

---

**Figure 3:** Evaluation of the library of copper-based complexes in photocatalytic alcohol–bromide conversion. Reactions irradiated with 394 nm light (pink) or 450 nm (blue). Front entries without an indicated phosphine ligand pertain to homoleptic Cu(diamine)$_2$BF$_4$ complexes and are colored in lighter blue. Entries without a color indicate reactions which could not be performed due to solubility or overoxidation of the complex.
(Table 1). As shown previously, a benzyl-protected alcohol 1 could be transformed to the corresponding bromide 2 in 99% yield, respectively (Table 1, entry 1). The corresponding bromide of citronellol (4) was also formed in high yield (91%, Table 1, entry 2). A long chain methyl ester 5 was also tolerated under the reaction conditions (98% of the bromide, Table 1, entry 3). The corresponding dibromide could be formed from 1,9-nonadiol (6) in quantitative yield (99%, Table 1, entry 4). A sulfur-containing alcohol 7 was smoothly converted to its bromide in 99% yield (Table 1, entry 5). An allylic alcohol 8 having a cis-olefin underwent alcohol-to-halide conversion in 89% yield and was isolated as a 1:1 mixture of cis and trans isomers (Table 1, entry 6). Finally, a racemic secondary alcohol 9 was easily transformed to the corresponding racemic bromide (99%, Table 1, entry 7).

Following the optimization of the catalyst structure and exploration of scope, the batch reaction conditions were then transferred to continuous flow (Table 2). Initially, an experimental set-up using a previously reported reactor for purple LEDs was selected for the reaction [30,31]. Following injection of the reaction mixture with a target residence time of 60 min, only traces of the desired bromide 2 were observed. Extending the residence time to 120 or 240 min increased the yield to 32–53%, but significant quantities of the starting alcohol 1 and the corresponding formate ester 3 were observed. Using tetra-n-butylammonium bromide (TBAB) as the halide source did not improve the yield, but resulted in larger amount of the formy-
lated product 3 (Table 2, entry 4). A possible explanation for the increased yield of 3 when using TBAB could be due to slower displacement of leaving group by the “bulkier” source of bromide. In attempting to extend the residence time, the flow rate of the reaction mixture was decreased. Knowing that faster flow rates can improve mixing and reaction rates [32], an additional reactor was placed in line and the residence time of 240 min was repeated but with an increased flow rate (110 μL/min, Figure 4 and Table 2 entry 5). Gratifyingly, the desired bromide 2 was isolated in 91% yield.

With optimized flow conditions in hand for the formation of bromides in continuous flow, five different alcohols were converted to their corresponding halides (Table 3). The benzyl-protected alcohol 1 could be transformed to the bromide in 83% yield (Table 3, entry 1), as was citronellol (4, 83% yield, Table 3, entry 2). A methyl ester 5, allylic alcohol 8 and racemic secondary alcohol 9 could all undergo conversion to their corresponding bromides in 240 min using the continuous flow protocol (Table 3, entries 3 to 5).

The continuous flow protocol was also applicable to the synthesis of anhydrides, which has also been previously reported by Stephenson and co-workers [33]. The carboxylic acid 10 was submitted to a flow protocol using the optimized Cu(tmp)(BINAP)BF₄ catalyst, CBr₄ (1 equiv) and 2,6-lutidine as base with a residence time of 20 min (Scheme 1). The anhydride derived from p-methoxybenzoic acid was isolated in 90% yield.

Conclusion
In summary, a heteroleptic copper-based photocatalyst Cu(tmp)(BINAP)BF$_4$ was discovered for the photochemical Appel-type conversion of alcohols to bromides, as well as carboxylic acids to their anhydrides. The protocol was highly efficient and could be adapted to continuous flow using purple LED reactors. The batch and continuous flow processes were all made possible due to the ability to screen highly modular copper-based complexes for photocatalysis.

Copper(I)-catalyzed tandem reaction: synthesis of 1,4-disubstituted 1,2,3-triazoles from alkyl diacyl peroxides, azidotrimethylsilane, and alkynes

Muhammad Israr¹,², Changqing Ye¹,², Munira Taj Muhammad¹, Yajun Li¹ and Hongli Bao*¹,²

Abstract
A copper-catalyzed azide–alkyne cycloaddition (CuAAC) reaction for the synthesis of 1,4-disubstituted 1,2,3-triazoles from alkyl diacyl peroxides, azidotrimethylsilane, and terminal alkynes is reported. The alkyl carboxylic acids is for the first time being used as the alkyl azide precursors in the form of alkyl diacyl peroxides. This method avoids the necessity to handle organic azides, as they are generated in situ, making this protocol operationally simple. The Cu(I) catalyst not only participates in the alkyl diacyl peroxides decomposition to afford alkyl azides but also catalyzes the subsequent CuAAC reaction to produce the 1,2,3-triazoles.

Introduction
The “click chemistry”, coined by K. B. Sharpless in 2001 [1], is a powerful chemical transformation that has rapidly orthogonalized traditional disciplinary boundaries. With the discovery of “click chemistry”, new fields have been opened for the research and synthesis of functionalized compounds that have applications in medicinal chemistry, drug discovery, materials chemistry, and as well as in bioconjugates [2-12].
can decompose spontaneously, with which the reactions are difficult or dangerous to handle [16]. Thus, a one-pot two-step process for the in situ generation of organic azides is highly required. A frequently used method to in situ generate organic azides is the azidation of organic halides, such as aliphatic halides, vinyl halides, or aromatic halides with sodium azide [24-27]. Organic triflates [28] and organic boronic acids [29-31] can also be used as alternative precursors for organic azides, when reacted with sodium azide. However, sodium azide is a highly toxic compound and has the potential to explode. Azidotrimethylsilane (TMSN$_3$) has been considered as a safer azide source, which actually has been successfully used in the CuAAC reaction directly [32-35], but rarely been used as an azido precursor to enrich the functionality of organic azide source. Moreover, as one of the most commonly appearing compounds in nature, carboxylic acids have rarely been directly used as the organic azide precursors for CuAAC reactions, considering the frequent involvement of organic halides. Thus, new methods with non or less toxic reagents and enriched organic azide sources for CuAAC reaction are still highly required.

Herein, we report a novel CuAAC reaction, using aliphatic carboxylic acids as the alkyl source [36], and TMSN$_3$ as the azide source (Scheme 1b). Because TMSN$_3$ can react with alkynes to form the CuAAC reaction product [32-35], there is one significant challenge of this method that need to be emphasized: how to control the reaction to generate the alkyl azides from aliphatic carboxylic acids and TMSN$_3$, before TMSN$_3$ directly reacting with alkynes.

Results and Discussion

Based on our unpublished work, we found that alkyl azide has always appeared as a side product when the reaction involved TMSN$_3$ and alkyl diacyl peroxide, easily available compounds derived from aliphatic carboxylic acids. With this information in mind, initially, we started our investigation with phenylacetylene (1a), commercially available lauroyl peroxide (2a), and TMSN$_3$ (Table 1). In a preliminary experiment, the reaction of 1a with 2a in the presence of 10 mol % of CuCl in THF at 50 °C afforded 1,4-disubstituted 1,2,3-triazole 3a in 65% isolated yield (Table 1, entry 1). Surprisingly, under these conditions no CuAAC product between TMSN$_3$ and phenylacetylene was detected. This result encouraged us to further exploit the optimization of the reaction conditions. Afterwards, the effect of the solvent was also investigated (Table 1, entries 2−8). Dichloromethane could afford the best result and the yield of the desired product 3a could be as high as 97% (Table 1, entry 2). Other metal salts of copper, such as Cu(OAc)$_2$, CuI, and CuBr were then examined and they showed lower catalytic efficiencies than that of CuCl (Table 1, entries 9−11). Moreover, a reduced amount of the catalyst loading leads to lower yields of product 3a (Table 1, entries 12−14).

With the optimized reaction conditions in hand, the scope of the terminal alkynes was screened and the results are depicted in Scheme 2. First, the reactivity of various substituted terminal arylalkynes was examined. Only 1,4-regioisomeric products were formed with good to excellent yields. Phenylacetylene with an electron-withdrawing bromo-, chloro-, or fluoro substituent afforded the corresponding products 3h−n in up to 92% yield, while phenylacetylenes with electron-donating...

*aReaction conditions: 1a (0.5 mmol), 2a (0.75 mmol), TMSN₃ (0.75 mmol), catalyst (mol %), solvent (2 mL), 50 °C, 10 h. b Yield was determined by ¹H NMR analysis. c Isolated yield in parentheses.

Tertiary alkyl dicarboxylic acid peroxides are relatively more reactive than primary and secondary alkyl dicarboxylic acid peroxides, but they are not stable enough for the simple filtration separation at room temperature. Thus, we have not tried the reactions with tertiary alkyl dicarboxylic acid peroxides.

In order to understand the mechanism of this reaction, we performed a set of experiments (Scheme 4). Firstly a radical capturing reaction was carried out with the addition of a radical trapping reagent (tetrakis(1,1,1,3,3,3-hexafluoro-2-propanoxy)loxy, TEMPO) [38,39] to the standard reaction system, no product 3a was obtained; only the radical trapped product 4 was detected by GC–MS (Scheme 4a).

To further investigate this phenomenon, we synthesized a substrate bearing a cyclopropylmethyl moiety, dicarboxylic acid peroxide 2p, which is a radical-clock [40,41]. The reaction of phenylacetylene with the dicarboxylic acid peroxide 2p afforded a ring-opened product 3pp in 88% yield. This result suggested the engagement of radical species in the reaction (Scheme 4b).

Based on the previous literature [16,42,43] and the above experimental findings, a possible reaction mechanism is suggested as shown in Scheme 5. In the presence of the Cu(I) catalyst, alkyl dicarboxylic acid peroxide decomposes into an alkyl radical, CO₂, and...
releases a carboxyl–Cu(II) complex, which undergoes a ligand exchange with azidomethylsilane to form azido–Cu(II) species. The alkyl radical then abstracts the azido moiety from the azido–Cu(II) species to afford an alkyl azide and the regenerated Cu(I) catalyst. Then, a conventional CuAAC process delivers the desired cycloaddition product 3.

**Conclusion**

In summary, we have established an efficient, ligand- and additive-free CuAAC reaction for the synthesis of 1,4-disubstituted 1,2,3-triazoles directly from a variety of readily accessible substrates such as alkyl diacyl peroxides, azidotrimethylsilane, and terminal alkynes. The alkyl carboxylic acids are for the first

Scheme 4: Preliminary mechanistic studies.
time being used as the alkyl azide precursors in the form of alkyl diacyl peroxides. This method avoids the necessity to handle organic azides, as they are generated in situ, making this protocol operationally simple. This reaction features a wide substrate scope, good functional group tolerance, high yields, and excellent regioselectivity. Most of all, the Cu(I) catalyst plays two roles in the reaction: decomposes the alkyl diacyl peroxides to afford the alkyl azides and catalyzes the subsequent CuAAC reaction to produce the 1,2,3-triazoles.

**Experimental**

**General procedure:** To a flame-dried Schlenk tube containing a magnetic stirring bar, terminal alkyne I (0.5 mmol), diacyl peroxide 2 (0.75 mmol), TMSN₃ (90.4 mg, 0.75 mmol), CuCl (4.9 mg, 0.05 mmol) and CH₂Cl₂ (2 mL) were added, respectively. The reaction mixture was stirred vigorously for 10 h at 50 °C. Then, the reaction mixture was cooled to room temperature, poured into saturated sodium bicarbonate solution (25 mL) and extracted with CH₂Cl₂ (3 × 25 mL). After drying over MgSO₄, the solvent was removed under reduced pressure in a rotary evaporator; the residue was purified by column chromatography on silica gel (PE/EA) to afford 3.

Abstract
The degenerative transfer of xanthates to olefins is enabled by the iridium-based photocatalyst [Ir{dF(CF₃)ppy}₂(dtbbpy)](PF₆) under blue LED light irradiation. Detailed mechanistic investigations through kinetics and photophysical studies revealed that the process operates under a radical chain mechanism, which is initiated through triplet-sensitization of xanthates by the long-lived triplet state of the iridium-based photocatalyst.

Introduction
A degenerative radical transfer of xanthates to olefins has been developed as a robust synthetic tool to create new C–C and C–S bonds in a single operation [1-13]. The method is featured by not only its capability of introducing a wide range of carbon substituents but also the ability of the installed xanthyl group in being transformed into a variety of functionalities [1-14]. This concept has also been of particular importance in the field of polymer science, known as reversible addition–fragmentation chain transfer (RAFT) polymerization [15,16]. Mechanistically, the degenerative transfer of xanthates 1 to olefins 2 proceeds through a radical chain mechanism, and thus requires an initial formation of carbon radicals A that add onto olefins 2. The subsequent reaction of the resulting alkyl radicals B with xanthates 1 provides xanthate adducts 3 with generation of carbon radicals A that maintain the radical chain (Scheme 1A). Peroxide initiators such as dilauroyl peroxide (DLP) are commonly utilized [1-14], while decomposition of DLP needs a high reaction temperature and inevitably generates considerable amounts of byproducts derived from DLP that sometimes require tedious purification of the desired products. A combination of triethylborane (Et₃B) and molecular oxygen can also initiate the reaction at lower temperature (e.g., room tempera-
ture), while the employment of Et$_3$B is hampered due to its pyrophoric nature under aerobic conditions as well as undesired Et$_3$B-mediated dextranthylation of α-xanthyl ketones [17-21]. As an alternative strategy, a light-driven approach has been developed [22-26], since the first degenerative transfer of xanthenes using S-benzoyl O-ethyl xanthate as a photo-cleavable initiator under tungsten lamp irradiation was reported by Zard [25,26] (Scheme 1B). However, these protocols have thus far adopted energy intensive light sources. Therefore, there is still ample room for establishing new protocols to realize the degenerative transfer of xanthenes onto olefins under user-friendly and milder reaction conditions. Herein, we report a photocatalytic degenerative radical transfer of xanthenes to olefins using an iridium-based photocatalyst under blue LED irradiation (Scheme 1C). A series of mechanistic investigations identified that the process involves a triplet-sensitization of the xanthenes by the long-lived triplet state of the iridium-based photocatalyst that triggers the radical chain process [27].

Results and Discussion

Over the last decade, there has been a remarkable advance in synthetic chemistry that takes advantage of various chromophores (either metallic or organic) having visible-light charge transfer absorption [28-37]. In the area of polymer synthesis, visible-light-induced RAFT polymerization of xanthenes with vinyl monomers under blue LED (light-emitting diode) irradiation has been reported [38-41]. Visible-light-induced single unit monomer insertion of the thiocarbonylthio compounds has also been developed for the synthesis of the sequence-controlled oligomers [41-45]. For example, the group of Boyer and Xu developed fac-Ir(ppy)$_3$ (6)-catalyzed polymerization of xanthate 4 with various vinyl monomers such as vinyl acetate, providing polymers of type 5 having a high molecular weight with a narrow molecular weight distribution. It was proposed that the polymerization is initiated by single-electron reduction of xanthate 4 by the highly reducing photo-excited state of fac-Ir(ppy)$_3$ (6) [46], although the details were not elucidated (Scheme 2) [39,40].

Based on these backgrounds, we wondered if the degenerative transfer of xanthates onto olefins could be facilitated by visible-light photocatalysis under milder reaction conditions. We therefore commenced our investigation with the reaction of ethyl ethoxycarbonylmethyl xanthate (1a) and 1-octene (2a) using fac-Ir(ppy)$_3$ (6) in DMSO under blue LED irradiation ($\lambda_{\text{max}} = 469$ nm, Table 1, entry 1). As expected, the desired xanthate transfer was observed, while the process efficiency was not very high, forming 3aa in only 58% yield with incomplete conversion even after stirring for 20 h. Interestingly, we found that the employment of the less reducing Ir catalysts 7 [46] and 8 [47] also worked for the process (Table 1, entries 2 and 3). Especially, the rather oxidizing [Ir{dF(CF$_3$)ppy)$_2$(dtbpy)}(PF$_6$) (8) resulted in full conversion of 1a, affording 3aa in 89% yield (Table 1, entry 3). Other photocatalysts, such as Ru(bpy)$_3$Cl$_2$ (9) [46], fluorescein (10) [48], and phenoxazine 11 [49], were not optimal for the present transformation (Table 1, entries 4–6). It should be noted that the reaction without the photocatalyst under visible light- and halogen lamp irradiation resulted in poorer conversion with formation of 3aa in only 10% and 30% yield, respectively, suggesting that the photocatalyst was important for the degenerative transfer of xanthate 1a (Table 1,
entries 7 and 8). On the other hand, the employment of a 365 nm UV lamp in place of the blue LED gave 3aa in 75% yield, although a slower reaction rate was observed compared to the optimal reaction conditions (Table 1, entry 9).

In principle, visible-light-mediated photocatalysis can serve for electron transfer (for either oxidation or reduction) and/or for energy transfer. We found that the reduction potential \( E_{p/2} \) of xanthate 1a is \(-1.78 \text{ V vs SCE} \), which is not sufficient to be reduced by the photoexcited states of Ir catalysts 6–8 (\( E_{1/2} \) of 6*, 7* and 8* = \(-1.73, -1.28, \) and \(-0.89 \text{ V vs SCE} \), respectively [46,47]). Apparently, photoinduced single-electron reduction of xanthate 1a by the photoexcited state of the optimal catalyst 8 is not feasible. In contrast, the triplet energy \( E_T \) of xanthate 1a was estimated as 57.5 kcal/mol by DFT calculation, that is close to those of photocatalysts 7 and 8 (\( E_T = 60.1 \text{ kcal/mol} \) [50]), indicating that the process could be initiated by the triplet sensitization pathway [51,52]. This assumption is in agreement with the lower process efficiency (Table 1, entry 1) observed in the reaction with fac-Ir(ppy)_3 (6) that possesses a lower triplet energy (\( E_T = 55.2 \text{ kcal/mol} \) [50]). The optimal photocatalyst 8 [47] has a longer excited state lifetime than 7 does [46], suggesting that the lifetime of the excited state of the photocatalyst is a key factor for the energy transfer mechanism.

To obtain a detailed mechanistic insight, steady-state photoluminescence (PL) quenching of photocatalyst 8 was examined using xanthate 1a and 1-octene (2a) as potential quenchers (Figure 1). The intensity of the PL peak of photocatalyst 8 (concentration of 8 was fixed as 25 \( \mu \text{M} \) solution in degassed DMSO for all the samples; for details see Supporting Information File 1) at 480 nm, arising from the radiative emission of the \( ^3\text{MLCT} \) state of the photocatalyst, was measured using 410 nm light excitation. When the concentration of xanthate 1a was gradually increased, a reduction in the PL intensity (I) of photocatalyst 8 was observed (Figure 1A). The Stern–Volmer plot of the ratio \( I_0/I \), where \( I_0 \) is the initial PL intensity in the absence of quencher, versus concentration of 1a showed a linear relationship with a quenching rate \( k_q = 1.25 \times 10^7 \text{ M}^{-1}\text{s}^{-1} \) (see Supporting Information File 1). On the other hand, the addition of 1-octene (2a, 40 mM), in place of xanthate 1a, resulted in only a small PL quenching of photocatalyst 8 (<8%, Figure 1B).

The time-resolved PL lifetime decay profiles of photocatalyst 8 (25 \( \mu \text{M} \) solution in degassed DMSO, 410 nm pulse excitation and monitoring emission at 480 nm) were recorded in the absence of a quencher, and in the presence of xanthate 1a and 1-octene (2a, 40 mM, Figure 1C). The lifetime profiles were described using a mono-exponential decay function with a lifetime of 1.40 \( \mu \text{s} \) in the absence of a quencher, and 1.03 and 1.37 \( \mu \text{s} \) in the presence of xanthate 1a and 1-octene (2a), respectively. The decrease in the PL lifetime of photocatalyst 8 in the presence of xanthate 1a suggests that they are interacting with each other. On the other hand, only a very weak interaction exists between 1-octene (2a) and the photocatalyst 8 as demonstrated by the insignificant PL quenching of the photocatalyst [53].

To obtain a detailed mechanistic insight, steady-state photoluminescence (PL) quenching of photocatalyst 8 was examined using xanthate 1a and 1-octene (2a) as potential quenchers (Figure 1). The intensity of the PL peak of photocatalyst 8 (concentration of 8 was fixed as 25 \( \mu \text{M} \) solution in degassed DMSO for all the samples; for details see Supporting Information File 1) at 480 nm, arising from the radiative emission of the \( ^3\text{MLCT} \) state of the photocatalyst, was measured using 410 nm light excitation. When the concentration of xanthate 1a was gradually increased, a reduction in the PL intensity (I) of photocatalyst 8 was observed (Figure 1A). The Stern–Volmer plot of the ratio \( I_0/I \), where \( I_0 \) is the initial PL intensity in the absence of quencher, versus concentration of 1a showed a linear relationship with a quenching rate \( k_q = 1.25 \times 10^7 \text{ M}^{-1}\text{s}^{-1} \) (see Supporting Information File 1). On the other hand, the addition of 1-octene (2a, 40 mM), in place of xanthate 1a, resulted in only a small PL quenching of photocatalyst 8 (<8%, Figure 1B).

\textsuperscript{a}The reactions were conducted using 0.3–0.5 mmol of xanthate 1a, 1-octene (2a, 2 equiv) and a photocatalyst in DMSO (1 M) at <30 °C with irradiation of a blue LED strip ($\lambda_{\text{max}} = 469$ nm, 15 W/m, 1.5 m) under an argon atmosphere. \textsuperscript{b}The values were obtained from references [46-50]. \textsuperscript{c}NMR yields using 1,1,2,2-tetrachloroethane as an internal standard. \textsuperscript{d}Isolated yield is stated in parentheses. \textsuperscript{e}Halogen lamp (300 W) was used in place of blue LED. \textsuperscript{f}Reaction was conducted at 40 °C. \textsuperscript{g}365 nm UV lamp (100 W) was used in place of blue LED.

The ns-TA spectra of xanthate 1a in degassed DMSO, measured using 355 nm pulse excitation, at various delay times show a broad band centered at ~620 nm (Figure 2C). This band has previously been ascribed to the absorption of the xanthic acid radical formed plausibly from homolytic C–S bond cleavage of the short-lived triplet state of xanthate 1a [22].

The ns-TA spectra of photocatalyst 8 (25 µM) in the presence of xanthate 1a (40 mM) in degassed DMSO at various delay times are shown in Figure 2D. The kinetic profile at 480 nm is described using a mono-exponential decay function with a quenched lifetime of 1.27 µs. The ca. 37% decrease in the lifetime of the excited $^3$MLCT state of photocatalyst 8 observed in the PL lifetime decay measurement (Figure 1C) and ns-TA kinetic measurement (Figure 2B) can be rationalized using
Figure 1: Photoluminescence (PL) spectra of the 7MLCT state of 8 in degassed DMSO solvent with (A) various concentrations of xanthate 1a added and (B) 40 mM of 1-octene (2a) added. The inset of (A) gives the Stern–Volmer plot of the corrected PL quenching at 480 nm. (C) Time-resolved PL lifetime decay profiles of photocatalyst 8 in degassed DMSO in the absence of quencher (square), presence of xanthate 1a (circle) and presence of 1-octene (2a, triangle). The mono-exponential decay fits are provided.

Figure 2: (A) ns-Transient absorption spectra of photocatalyst 8 in degassed DMSO recorded at different delay times (excitation wavelength = 355 nm). (B) ns-TA kinetic profile probed at 480 nm for photocatalyst 8 in the absence and presence of xanthate 1a. (C) and (D) ns-Transient absorption spectra of xanthate 1a and 8 in the presence of 1a in degassed DMSO recorded at different delay times, respectively (excitation wavelength = 355 nm).
either an energy-transfer or an electron-transfer mechanism. For the same delay times and in the presence of 1a, the ΔOD values in Figure 2D are smaller than those of photocatalyst 8 in the absence of the xanthate (Figure 2A). This is due to the quenching of the 3MLCT state of the photocatalyst. If an electron-transfer process occurs from photocatalyst 8 to xanthate 1a, the ΔOD values in the UV region should be noticeably higher due to the TA band contribution from bpy− connected to an Ir metal center of the +4 oxidation state (i.e., absorption due to [IrIV{dF(CF3)ppy}2](dtbpy−)) species [55]. However, this was not observed in Figure 2D; suggesting that quenching is due to energy transfer rather than electron transfer, and in agreement with the thermodynamic consideration where single-electron reduction of xanthate 1a likely does not proceed with the excited photocatalyst 8. We therefore propose that the observed PL quenching is due to energy transfer from the excited 3MLCT state of photocatalyst 8 to the triplet state of xanthate 1a. When comparing the normalized TA spectra of photocatalyst 8 in the absence and presence of xanthate 1a (see Supporting Information File 1, Figure S4), an additional contribution from a broad ΔOD band that stretches from 500 nm to 800 nm is seen for the latter which is attributed to the absorption of the xanthic acid radical. In this case, the xanthic acid radical is formed from the homolytic bond cleavage of the excited triplet state of 1a formed by direct 355 nm laser light excitation and triplet–triplet energy transfer involving the excited photocatalyst 8.

To confirm the possibility of a direct photoexcitation of xanthate 1 using blue LED light irradiation as an alternative mechanism, a steady-state UV–vis absorption spectroscopy study of xanthate 1a was conducted (Figure 3). The UV–vis absorption spectrum of 1a (1 mM in DMSO) showed absorption bands at 340–390 nm assigned to the n→π* electronic transition of the C=S bond as a characteristic peak of thiocarbonyl containing compounds [56]. In fact, the reaction of 1a and 2a under 365 nm UV lamp irradiation without a photocatalyst delivered product 3aa in 75% yield (Table 1, entry 9). This indicates the excitation of xanthate 1a through an n→π* electronic transition of the C=S bond is in operation in the UV irradiation process. The involvement of a radical chain mechanism was further confirmed by calculating the quantum yield (Φ) because a chain process provides multiple equivalents of product per photon absorbed by the photocatalyst (Φ > 1). The photon flux of blue LED (λmax = 469 nm) was determined using the potassium ferrioxalate actinometer [57,58]. After irradiation of the mixture of xanthate 1a and olefin 2b under optimal reaction conditions with blue LED light irradiation for 4 h (Scheme 3), product 3ab was obtained in 58% yield. This is consistent with 12 equivalents of xanthate adduct 3ab produced per photon absorbed by the photocatalyst 8 (Φ = 12).

On the basis of these observations, a proposed triplet sensitization mechanism is illustrated in Scheme 4. In this reaction, photocatalyst 8 serves as a catalyst of an initiation step through energy transfer from photoexcited 8* to xanthate 1 to form excited xanthate 1* and regeneration of 8 in the ground state [59-61]. The resulting excited xanthate 1* induces homolytic scission of the C=S bond to generate the stabilized S-radical and C-radical A, which then enters the innate radical chain-propagation mechanism to provide xanthate adduct 3. It is worth noting that at the wavelength of the light source used (469 nm), xanthate 1a absorbs a negligible amount of light (Figure 3) and the majority of triplet 1a formed is due to energy transfer from excited catalyst 8*.

![Scheme 3: Determination of quantum yield.](image-url)
Having optimized the reaction conditions on the photocatalytic degenerative transfer of xanthates, we next explored the scope of olefins 2 using xanthate 1a (Table 2). The present method tolerated a variety of functionalities such as acetyl, cyano, silyl, ethoxy, N-Boc amino, boryl, hydroxy, and halogen groups, affording xanthate adducts 3ab–ai in good yields (Table 2, entries 1–8). We found strained 1,1-disubstituted olefins such as methylenecyclopropane 2j and methylenecyclobutane (2k) are amenable to the current protocol (Table 2, entries 9 and 10), whereas the reaction of methylenecyclopentane (2l) afforded not only the desired xanthate adduct 3al in 60% yield but also the substituted cyclopentene 3al' in 18% yield (Table 2, entry 11), implicating that the redox process is partially operating along with the main radical chain process. Norbornene (2m) was found reactive for degenerative transfer of xanthate 1a (Table 2, entry 12). The reaction was also applied to dienes 2n and 2o, which led the formation of functionalized cyclopentane 3an and pyrrolidine 3ao, respectively, via 5-exo-trig radical cyclization (Table 2, entries 13 and 14). The present method was capable in functionalizing olefins 2p and 2q installed on steroid scaffolds with high efficiency (Table 2, entries 15 and 16).

We next examined the reactions of various xanthates 1 with allyl acetate (2b, Table 3). The reactions of ketonyl xanthates having phenyl, para-bromophenyl, methyl, cyclopropyl, N,O-dimethyl acetylhydroxamate, and chloromethyl moieties proceeded smoothly, producing xanthate adducts 3bb–gb in good yields (Table 3, entries 1–6). Notably, the photocatalyst-

Cally cleavable aryl bromide (Table 3, entry 2) and the α-chlorocarbonyl moiety (Table 3, entry 6) were also stable under the current reaction conditions [62,63]. Furthermore, double addition of bisxanthate 1h was successfully achieved in the presence of 5 equiv of olefin 2b, giving 3hb in 69% yield (Table 3, entry 7). This method is also suitable for generating α-aminoalkyl radicals from phthalimidomethyl and succinimidomethyl xanthates [64], as well as α-trifluoromethylamino xanthate 1k [65] to afford desired products 3ib–kb in good to moderate yields (Table 3, entries 8–10).

**Conclusion**

We have established a protocol for a photoinduced radical addition of xanthates to olefins using an iridium-based photocatalyst.
lyst under blue LED irradiation, leading to diverse xanthate adducts. This reaction proceeds through a radical-chain propagation mechanism via an initiation involving a triplet-sensitizer process of xanthates by an excited iridium-based photocatalyst.

Tandem copper and photoredox catalysis in photocatalytic alkene difunctionalization reactions

Nicholas L. Reed, Madeline I. Herman, Vladimir P. Miltchev and Tehshik P. Yoon*

Abstract

Oxidative alkene difunctionalization reactions are important in synthetic organic chemistry because they can install polar functional groups onto simple non-polar alkene moieties. Many of the most common methods for these reactions rely upon the reactivity of pre-oxidized electrophilic heteroatom donors that can often be unstable, explosive, or difficult to handle. Herein, we describe a method for alkene oxyamination and diamination that utilizes simple carbamate and urea groups as nucleophilic heteroatom donors. This method uses a tandem copper–photoredox catalyst system that is operationally convenient. The identity of the terminal oxidant is critical in these studies. Ag(I) salts proved to be unique in their ability to turn over the copper cocatalyst without deleteriously impacting the reactivity of the organoradical intermediates.

Introduction

Over the past decade, a renewed interest in synthetic photochemistry has resulted in the discovery of a broad range of powerful new bond-forming transformations [1-4]. Much of this work has been premised on the ability of visible light-activated photocatalysts to generate highly reactive odd-electron intermediates via photoinduced electron transfer processes. A major theme of research that has emerged from these studies is the application of various cocatalysts to intercept the organoradical intermediates of photoredox reactions and modulate their subsequent reactivity [5,6]. The combination of photoredox catalysis with transition metals, Lewis acids, and organocatalysts has been productively utilized in asymmetric transformations [7-9], cross-couplings [10-12], and oxidative decarboxylation reactions [13,14], among others. The use of a cocatalyst to control these photochemical transformations enables reactions that are not accessible from the native reactivity of the organoradical intermediates by themselves.

Our laboratory is interested in the design of photochemical strategies for oxidative functionalization reactions [15,16]. We recently described [17] a new approach to alkene difunctionalization that combines the photoredox activation of electron-rich
alkenes with copper(II)-mediated oxidation of electron-rich radicals as described by Kochi [18-20]. These studies resulted in the development of a general new protocol for oxyamination (Figure 1a) and diamination (Figure 1b) of alkenes. The mechanism we have proposed for photocatalytic oxyamination is outlined in Figure 1c. Photoinduced one-electron oxidation of an appropriately electron-rich styrene 1 results in the formation of a radical cation 1•⁺ that is susceptible to attack by various heteroatomic nucleophiles, including carbamates [21,22]. Subsequent oxidation of radical 7 by Cu(II) affords a formally cationic intermediate that is trapped by the carbamoyl oxygen to afford oxonium 8. The loss of the tert-butyloxycarbonyloxycarbonyl cation provides the oxyamination product 2, which can be isolated in good yields with excellent diastereoselectivity. Turnover of the photocatalyst can be coupled to the reduction of Cu(I) to Cu(0), which can be observed precipitating from solution over the course of the reaction.

Copper(II) salts have been demonstrated to be convenient terminal oxidants in a variety of synthetically useful catalytic reactions [23-26]. They are easily handled, are available from commodity chemicals for nominal cost, and present minimal environmental and health concerns in large-scale applications. The use of stoichiometric copper(II) reagents, however, could become prohibitive in certain applications where specific, synthetically laborious ligand sets might be required, as in enantioselective catalytic oxidation reactions or certain cross-coupling applications. We wondered, therefore, if catalytic loadings of copper(II) salts might be used in these reactions by adding a secondary terminal oxidant to turn over the intermediate.
Results and Discussion

A range of mild oxidants can oxidize copper(I) to copper(II), and the use of dioxygen for this purpose is frequently exploited to effect synthetically useful copper-catalyzed aerobic oxidation reactions [27,28]. However, the use of molecular oxygen as a terminal oxidant presents unique challenges in photoredox chemistry. Triplet dioxygen rapidly quenches the excited state of most common photoredox catalysts [29-31], decreasing their effective lifetimes and producing singlet dioxygen or superoxide, which can react destructively with many common organic functional groups. Moreover, the organoradical intermediates that characterize much of photoredox chemistry can react rapidly with ground-state dioxygen to afford unstable hydroperoxy radicals that can also decompose unproductively [32,33]. Indeed, in our previous study of photocatalytic alkene difunctionalization, we found that dioxygen and similar commonly used terminal oxidants resulted in unproductive decomposition of the substrates [17], and that Cu(II) oxidants were uniquely suitable in this application. At the outset of this investigation, therefore, we imagined that the identification of a co-oxidant for use with catalytic Cu(II) might face similar practical constraints. Ideally, we hoped to identify a terminal oxidant that would be compatible with the chemistry of the radical intermediates, would not generate any highly reactive oxygen species, and would not produce toxic or chromatographically problematic byproducts.

As a starting point for our optimization studies, we examined the intramolecular oxyamination of carbamate 1 (Table 1), a reaction we had previously studied under stoichiometric Cu(II) conditions and found to proceed in good yield using 2.5 mol % 2,4,6-triphenylpyrylium tetrafluoroborate (TPPT, 3) as a photocatalyst and 1.2 equiv of Cu(TFA)₂ as a stoichiometric oxidant. We lowered the loading of Cu(TFA)₂ to 10 mol % and assessed the effect of a series of alternate oxidants that have been used in other copper-catalyzed oxidation reactions. Most failed to produce significant quantities of the desired product (Table 1, entries 1–3). As expected, the use of oxygen as a terminal oxidant resulted in rapid conversion of 1 to an intractable mixture of decomposition products, with only trace formation of the desired oxyamination product (Table 1, entry 1). Other oxidants afforded less decomposition but were not effective in turning over the Cu(II) cocatalyst (Table 1, entries 2 and 3). Of all of the oxidants screened, silver(I) salts were found to be uniquely effective at mediating turnover of the copper(II) catalyst [34-36]. After screening commercially available silver(I) salts, Ag₂CO₃ was found to be the optimal terminal oxidant (Table 1, entry 5). There is a competitive silver-mediated photodecomposition process that consumes the starting alkene unproductively, and thus the copper(II)/silver(I) ratio was tuned to optimize the efficiency of the desired oxyamination process (Table 1, entries

⁹All reactions were conducted in degassed CH₂Cl₂ and irradiated with a 15 W blue LED flood lamp for 2 h. Yields were determined by ¹H NMR analysis of the unpurified reaction mixtures using phenanthrene as an internal standard. ³No TPPT. ⁵No light.
Optimal conditions were found to be 2.5 mol % TPPT, 30 mol % Cu(TFA)$_2$, and 1 equiv Ag$_2$CO$_3$ in CH$_2$Cl$_2$ (Table 1, entry 7). Finally, control experiments validated the necessity of each reaction component. Minimal product formation was observed when Cu(TFA)$_2$, Ag$_2$CO$_3$, TPPT, or light were omitted from the reaction (Table 1, entries 8–11), confirming that the combination of photoredox and copper(II) catalysis is critical to achieve good reactivity.

We found that these optimized reaction conditions are applicable to both oxyamination and diamination reactions. Experiments probing the scope of these transformations are summarized in Figure 2. A range of styrenes bearing varying electron-donating and electron-withdrawing substituents smoothly undergo oxyamination (9–12), as do ortho-substituted styrenes (13). The presence of an electron-rich heterocycle is also tolerated (14), without any evidence of oxidative decomposition of this sensitive functional group. Modifications to the alkyl tether (15) did not adversely affect the reaction. Intermolecular oxyamination of styrenes is also feasible using these conditions. While simple styrenes polymerize rapidly under these conditions, a range of β-substituted styrenes undergo smooth oxyamination using tert-butyl carbamate as the nucleophilic nitrogen atom source (16–18). Finally, alkene diamination is also readily achieved using N-phenylureas as nucleophiles, although acridinium photocatalyst 6 afforded modestly higher yields in these reactions (19–21).

A complete mechanistic picture of this reaction will require additional experimentation; however, control experiments demonstrate that Ag$_2$CO$_3$ is not a competent terminal oxidant on its own (Table 1, entry 9) and that the presence of Cu(II) is critical for the oxyamination to occur (Table 1, entry 8). Moreover, our previous studies demonstrated that Cu(II) can serve as a competent terminal oxidant in a stoichiometric fashion. Thus, it seems clear that the role of the Ag(I) additive in this reaction is to re-oxidize Cu(I) to Cu(II), and that the Cu(II) salt in this transformation is indeed a cocatalyst for the oxidative difunctionalization of styrenes. Efforts to render this transformation enantioselective by utilizing chiral Cu(II) complexes have thus far not been successful. A screen of several classes of privileged ligands for asymmetric copper catalysis produced only racemic oxyamination products. We interpret this observation as an indication that Cu(II) is unable to control the stereochemistry of the C–N bond-forming step, as one might expect from its proposed role in radical oxidation (Figure 1C).

**Conclusion**

These studies have demonstrated that the copper-mediated alkene difunctionalization reactions recently reported by our laboratory can be rendered catalytic in Cu(II) by adding a secondary terminal oxidant, and that Ag(II) salts appear to be uniquely effective in this capacity. This work thus provides a platform for the development of enantioselective photocatalytic alkene difunctionalization reactions that can use a chiral Cu(II) complex as a substoichiometric catalyst rather than as a terminal oxidant. Moreover, much of the utility of photoredox catalysis has been predicated on its ability to generate radical intermediates under mild and operationally convenient conditions. The ability to intercept transient photogenerated organoradical intermediates and divert them towards carbocation reactivity is an intriguing paradigm for the expansion of photoredox chemistry.
towards net oxidative transformations. Current studies in our laboratory are investigating the further application of copper cocatalysts to a wide range of alternate photoredox-mediated oxidative transformations.

A diastereoselective approach to axially chiral biaryls via electrochemically enabled cyclization cascade

Hong Yan¹, Zhong-Yi Mao¹, Zhong-Wei Hou¹, Jinshuai Song² and Hai-Chao Xu*¹

Abstract

A diastereoselective approach to axially chiral imidazopyridine-containing biaryls has been developed. The reactions proceed through a radical cyclization cascade to construct the biaryls with good to excellent central-to-axial chirality transfer.

Introduction

Axially chiral biaryls are prevalent in natural products, bioactive molecules and organocatalysts [1,2]. Among the many methods that have been developed for the synthesis of chiral biaryls [3-10], reactions that take advantage of the central-to-axial chirality transfer have been less explored [11-14]. In addition, an antroposelective synthesis of imidazopyridine-based biaryls has not been reported.

Nitrogen-centered radicals (NCRs) are attractive reactive intermediates for organic synthesis as they provide opportunities for the efficient construction of C–N bonds [15-19]. Recently, the generation of NCRs through electron transfer-based methods has been attracting attention. Organic electrochemistry is a powerful tool for adding or taking electrons from organic molecules to promote redox reactions because of its reagent-free feature and the tunability of electric current and potential [20-30]. We [31-34] and others [35-41] have studied the reactions of electrochemically generated NCRs. Particularly, we have recently reported an electrochemical synthesis of imidazo-fused N-heteroaromatic compounds via a radical cyclization cascade [31]. Building on this work, we report herein an antroposelective synthesis of imidazopyridine-containing biaryls via central-to-axial chirality transfer (Scheme 1).

Results and Discussion

The substituents on the phenyl ring (R¹) and at the propargylic position (R²) of carbamate 2 were varied to study their effects on the diastereoselectivity (Table 1). The electrolysis was con-
ducted under previously established conditions employing a three-necked round-bottomed flask as the cell, a reticulated vitreous carbon (RVC) anode and a platinum plate cathode [31]. The reaction was carried in refluxing MeCN/H$_2$O (9:1) with tetraarylhydrazine 1 as the redox catalyst, NaHCO$_3$ (2 equiv) as an additive, and Et$_4$NBF$_4$ (1 equiv) as the supporting electrolyte. These investigations indicated that bulky tertiary groups at both R$_1$ and R$_2$ positions were needed to ensure efficient chirality transfer. Hence, carbamate 2a (Table 1, entry 1) bearing a t-Bu group at R$_1$ and R$_2$ positions, respectively, reacted to give imidazopyridine-based biaryl 3a in 68% yield with good diastereoselectivity (14:1 dr). Replacing the t-Bu group at the propargylic position with iPr (Table 1, entry 2) or on the phenyl ring with Ph (Table 1, entry 3) or OiPr (Table 1, entry 4) all resulted in low diastereoselectivity (2:1 to 3:1).

The scope of the electrosynthesis was investigated by varying the peripheral substituents of the carbamate substrate 2 (Scheme 2). The pyridyl ring could be substituted at positions 4, 5 and 6 with a range of substituents with diverse electronic properties such as OMe (3e), Br (3f), CF$_3$ (3g), CN (3h), Cl (3i), and Me (3j). Pyridyl rings bearing multiple substituents were also tolerated (3k and 3l). The stereochemistry of the biaryl product was determined by obtaining an X-ray crystal structure of 3k. The t-Bu-substituted phenyl ring on the alkyne moiety containing an extra OMe (3m) or Me (3n and 3o) group was tolerated albeit with reduced diastereoselectivity. The t-Bu group on the phenyl ring and at the propargylic position could be replaced with other bulky tertiary substituents to afford a range of functionalized biaryl products (3p–w). The electrochemical conditions were compatible with several functional groups including aryltrimethylsilane (3p), silyl ether (3q–s), ester (3t) and cyclic ketal (3u). Note that all the diastereomers were separable by flash column chromatography. Heating a solution of the major isomer of 3n in MeCN at 80 °C for 4 h did not lead to isomerization, suggesting that the stereoselectivity of the reaction was not controlled by relative thermodynamic stability of the diastereomers. The major isomer of 3c, which contained a sterically less demanding Ph group at the R$_1$ position (cf. Table 1), did not isomerize at room temperature for 1 year. However, heating a solution of this compound in MeCN

at 80 °C for 4 h resulted in a mixture of diastereomers in a ratio of 3:1. These results suggest that the sterically demanding substituents at R\textsuperscript{1} and R\textsuperscript{2} positions (cf. Table 1) are critical to ensure good stereoselectivity during the product formation and to prevent isomerization after the reaction.

A mechanism for the electrochemical synthesis was proposed based on the results from our previous work [31] and of this work (Scheme 3). The redox catalyst 1 is oxidized at the anode to give radical cation I. In the meanwhile, H\textsubscript{2}O is reduced at the cathode to afford HO\textsuperscript{−} and H\textsubscript{2}. The base generated at the cathode deprotonates 2a to give its conjugate base II. The anionic II is oxidized by radical cation I through single electron transfer (SET) to give radical intermediate III, which undergoes a bicyclization to give V. Further oxidation of V followed by hydrolysis of the cyclic carbamate moiety leads to the formation of 3a.

Based on the proposed reaction mechanism and the results mentioned above, the cyclization of vinyl radical IV to give V is the atroposelective step. Density functional theory (DFT)-based calculations suggested that the cyclization of IV could be explained by a Curtin–Hammett scenario (Scheme 4) [42]. Specifically, the equilibrium of the conformations IV and IV′ is

Scheme 3: Proposed reaction mechanism for the electrochemical synthesis of 3a.

Scheme 4: Computation investigation on the vinyl radical cyclization. DFT (M06-2X/6-31G*) calculated energetics (kcal mol\textsuperscript{−1}) are Gibbs free energies in MeCN.
much faster than their respectively cyclizations to give V and V*. Since TS2 is relatively lower in energy than TS3, V is formed as the major product.

Conclusion
In summary, we have developed a diastereoselective approach for the synthesis of axially chiral biaryls through an electricity-powered cyclization cascade. The reactions employ easily assembled starting materials and afford functionalized imidazo-pyridine-based biaryls in good to high yields and diastereoselectivity.

Photochemical generation of the 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical from caged nitroxides by near-infrared two-photon irradiation and its cytotoxic effect on lung cancer cells

Ayato Yamada^1, Manabu Abe^*1,2,3, Yoshinobu Nishimura^*4, Shoji Ishizaka^1,2, Masashi Namba^2,5, Taku Nakashima^2,5, Kiyofumi Shimoji^5 and Noboru Hattori^*2,5

Abstract

Novel caged nitroxides (nitroxide donors) with near-infrared two-photon (TP) responsive character, 2,2,6,6-tetramethyl-1-(1-(2-(4-nitrophenyl)benzofuran-6-yl)ethoxy)piperidine (2a) and its regioisomer 2b, were designed and synthesized. The one-photon (OP) (365 ± 10 nm) and TP (710–760 nm) triggered release (i.e., uncaging) of the 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical under air atmosphere were discovered. The quantum yields for the release of the TEMPO radical were 2.5% (2a) and 0.8% (2b) in benzene at ≈1% conversion of 2, and 13.1% (2a) and 12.8% (2b) in DMSO at ≈1% conversion of 2. The TP uncaging efficiencies were determined to be 1.1 GM at 740 nm for 2a and 0.22 GM at 730 nm for 2b in benzene. The cytotoxic effect of compound 2a on lung cancer cells under photolysis conditions was also assessed to test the efficacy as anticancer agents. In a medium containing 100 μg mL^{-1} of 2a exposed to light, the number of living cells decreased significantly compared to the unexposed counterparts (65.8% vs 85.5%).
Introduction

Nitroxides (aminoxyl radicals) possess a delocalized unpaired electron and exhibit negligible dimerization reactivity, making them persistent open-shell species [1-4]. In addition to their ease of handling, nitroxides are highly sensitive to electron paramagnetic resonance (EPR) spectroscopy and redox reactions. Therefore, nitroxides have been developed and utilized in diverse and crucial applications, not only in chemistry, but also in biology, physiology, and energy sciences. These applications include spin-labels [5-7], fluorophore-nitroxide probes [8], contrast agents in magnetic resonance imaging (MRI) [9], polarization transfer agents for nuclear magnetic resonance (NMR) [10-13], and radical batteries [14,15]. Furthermore, the efficient synthesis of polymers with narrow molecular mass distributions has been accomplished using nitroxides as a mediator, i.e., so-called nitroxide-mediated polymerization (NMP) [16-20], and the nitroxide-mediated synthesis of ketones from alcohols is also well utilized in organic synthesis [21-25]. The huge number of studies concerning nitroxides clearly indicates the importance of new methods of generating nitroxides for the future development of science and technology. Notably, in physiological studies [26-32], spatiotemporal control of nitroxide generation is a key approach for investigating the role of redox-active nitroxides in mediating oxidative stress in organisms [27-32].

In 1997, Scaiano and co-workers reported the triplet-xanthone sensitized generation of the 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical from alkoxyamine under ultraviolet (355 nm) irradiation (Scheme 1) [33]. De-aerated conditions are necessary for the triplet-sensitized generation of TEMPO due to the triplet quenching ability of O₂. The polymerization reactions were initiated via photochemical reaction [34-36]. For physiological studies, however, the photochemical release of nitroxides should be achieved in the presence of O₂. Thus, the triplet sensitized method may not be useful for physiological studies. The application of alkoxyamines as theranostic agents [37-40] has been proposed and reported by Brémont and co-workers [41,42].

Near-infrared (NIR) photons are excellent light sources in physiological studies as this wavelength of light is less harmful to living tissue than ultraviolet irradiation. Deeper penetration of NIR photons into biological samples is possible using NIR radiation with wavelengths of 650–1050 nm (= 27–44 kcal mol⁻¹). However, in general, chromophores do not absorb at such long wavelengths and the photon energy is too low for bond-cleavage reactions to generate (i.e., uncage) functional molecules. For example, the bond-dissociation energy of the weak PhCH₂–OPh, linkage is reported to be 52.1 kcal mol⁻¹ [43]. These issues can be solved by using the NIR-two-photon (TP) excitation technique [44], in which a molecule is electronically excited to the same state generated by one-photon (OP) excitation in the UV–vis region [45]. In addition to the advantages of TP excitation, three-dimensional control of the electronic excitation is possible because the probability of TP excitation is proportional to the square of the light intensity [46]. The light-induced generation of nitroxides using the TP excitation technique, i.e., the concentration jump of nitroxides, is one promising method of exploring the role of these species in life phenomena [47-54] and of promoting site-selective chemical reactions such as polymerization. Very recently, Guillaumeau and co-workers reported the two-photon-induced release of nitroxides in a materials science study [55].

In the last decade, we developed a TP-responsive photo-labile protecting group [56-58] with simple cyclic stilbene structures such as 2-(4-nitrophenyl)benzofuran (NPBF) that absorb in the NIR region of 710–760 nm for the uncaging of bioactive substances such as glutamate and Ca²⁺ [59-64]. Herein, we report the synthesis of new caged nitroxides (nitroxide donors) 2a and 2b having the TP-responsive NPBF chromophore and the NIR TP-triggered generation of the 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical under atmospheric conditions using these species (Scheme 1). Because free radicals are cytotoxic due to their strong DNA-damaging activity [65], they play important roles as anticancer therapeutic agents [66]. Among the free radicals, nitroxides including the TEMPO radical have unique properties, where they can act not only as radical scavengers, but also as anticancer agents [67]. Due to the unique properties described above, nitroxides are not toxic to normal host cells and exhibit toxicity only to tumor cells. Thus, nitroxides are ideal candidates as anticancer therapeutic agents. Based on this knowledge, the cytocidal effect of the
radical released from compound 2a on lung cancer cells was tested in vitro, in addition to the fundamental study.

Results and Discussion
The caged-TEMPOs 2a and 2b were synthesized as shown in Scheme 2. The new compounds, 5-ethyl- and 6-ethyl-2-(4-nitrophenyl)benzofuran (5a and 5b), were synthesized from 1-ethynyl-4-nitrobenzene (4) that was prepared from the commercially available 1-iodo-4-nitrobenzene (3) [68]. The TEMPO moiety was introduced at the benzylic position of 5a and 5b using the copper-catalyzed radical reaction in the presence of tert-butyl hydroperoxide (TBHP) to afford 2a and 2b in 38% and 52% yield, respectively [69]. The caged TEMPOs 2a and 2b were thermally stable in benzene below 320 K (47 °C), as confirmed by electron paramagnetic resonance (EPR) spectroscopic analysis. Significant thermal decomposition of 2a and 2b was observed at ≈340 K (67 °C), as indicated by the typical EPR signals (see Supporting Information File 1, Figure S1).

The photophysical data for the new compounds 2a,b and 5a,b are summarized in Table 1. The absorption maxima of compounds 2 and 5 were observed at ≈370 nm with a molar extinction coefficient ε ≈20000 M⁻¹ cm⁻¹ in both benzene and DMSO. The emission profile showed a significant solvent effect. The fluorescence quantum yields in DMSO of 5a and 5b were determined to be 16.1 and 8.6%, respectively, although no emission was observed from these compounds in non-polar benzene, indicating that the excited state has zwitterionic character. The charge transfer transition was supported by time-dependent density functional theory (TD-DFT) calculations for 5a at the CAM-B3LYP/6-31G(d) level of theory (Supporting Information File 1, Figure S2). The fluorescence quantum yields of caged-TEMPO 2a and 2b were found to be 2.9 and 2.2% in DMSO, which are much smaller than those of 5a and 5b, respectively, suggesting the chemical reactivity of the singlet excited states of 2a and 2b.

Time-correlated single photon counting (TCSPC) measurement was performed at 298 K in DMSO to estimate the fluorescence lifetime (τ) of 2 and 5 (Table 1). Single-exponential decay curves were observed for 5a and 5b, respectively (Supporting Information File 1, Figure S3). The lifetimes determined by

aAbsorption maximum of 2a, 2b, 5a, 5b. bEmission maximum of 2a (1.18 × 10⁻⁶ M), 2b (1.18 × 10⁻⁶ M), 5a (1.16 × 10⁻⁶ M), 5b (1.12 × 10⁻⁶ M).

cFluorescence quantum yields. The standard sample 9,10-diphenylanthracene (Φ_f = 0.91) was used for determining the quantum yields.

dFluorescence lifetime monitored at 560 nm. The concentrations were the same as those used for the fluorescence measurements. eEach contribution is 57% and 43%, respectively. fEach contribution is 70% and 30%, respectively.
Figure 1: Photochemical generation of TEMPO from 2a and 2b. EPR spectra acquired during the photolysis of 2a (5 mM) in benzene using 365 nm LED light under air atmosphere.

Figure 2: Time profile for photochemical generation of TEMPO radical from 2 (5 mM) at ≈298 K in benzene: (a) from 2a under degassed conditions, (b) from 2b under degassed conditions, (c,g) from 2a under air conditions, (d,h) from 2b under air conditions, (e) from 2a under O₂, (f) from 2b under O₂.

Single-exponential fitting were 1430 (5a) and 870 ps (5b), respectively (Table 1, entries 3 and 4). Double-exponential decay was, however, observed for the TEMPO-substituted NPBF derivatives 2a and 2b, where the lifetimes were 220 (57%) and 1370 ps (43%) for 2a, and 390 (70%) and 890 ps (30%) for 2b (Table 1, entries 1 and 2). For 2a and 2b, intermolecular charge transfer processes induced by the TEMPO moiety may account for the double-exponential decay curves to some extent.

OP photolysis of 2a (5 mM) was first conducted in benzene at ≈298 K using 365 nm light (6.02 × 10¹⁵ photons s⁻¹) under atmospheric conditions (Figure 1). Clean release of the TEMPO radical was confirmed by measuring the electron paramagnetic resonance (EPR) signals of the typical nitroxide, \( A_N = 15.5 \) G \( (g = 2.00232, \) Figure 1 and Figure 2c). The first-order rate constant for generation of TEMPO in the bulk photoreaction was found to be \( k = 1.6 \times 10^{-5} \) s⁻¹. The amount of photochemically released TEMPO radical was determined by comparing the EPR intensity with the calibration curve of the standard TEMPO sample (Supporting Information File 1, Figure S4). The chemical yield of TEMPO was 80% after 10 min irradiation in benzene under air atmosphere (Figure 2g). Secondary photoreaction of TEMPO gradually decreased the chemical yield of TEMPO. The quantum yield (\( \Phi \)) for photochemical release of the TEMPO radical was 2.5% at ≈1% conversion in the photolysis of 2a in benzene under atmospheric conditions. Similar photochemical generation of the TEMPO radical was conducted with 2b (5 mM, Supporting Information File 1, Figure S5 and Figure 2d,h). The clean generation of the TEMPO radical was also observed during photolysis under 365 nm irradiation in benzene at ≈298 K under atmospheric conditions, although the reaction was slower than that of 2a, \( k = 5.5 \times 10^{-6} \) s⁻¹; \( \Phi = 0.8\% \) at ≈1% conversion of 2b. However, the chemical yield of TEMPO was also high (81% after 20 min irradiation under the same conditions), although slow photochemical decomposition of TEMPO was observed with prolonged irradiation (Figure 2h). In DMSO, the quantum yield for TEMPO was 80% after 10 min irradiation in benzene under air atmosphere (Figure 2g). Secondary photoreaction of TEMPO gradually decreased the chemical yield of TEMPO. The quantum yield (\( \Phi \)) for photochemical release of the TEMPO radical was 2.5% at ≈1% conversion in the photolysis of 2a in benzene under atmospheric conditions. Similar photochemical generation of the TEMPO radical was conducted with 2b (5 mM, Supporting Information File 1, Figure S5 and Figure 2d,h). The clean generation of the TEMPO radical was also observed during photolysis under 365 nm irradiation in benzene at ≈298 K under atmospheric conditions, although the reaction was slower than that of 2a, \( k = 5.5 \times 10^{-6} \) s⁻¹; \( \Phi = 0.8\% \) at ≈1% conversion of 2b. However, the chemical yield of TEMPO was also high (81% after 20 min irradiation under the same conditions), although slow photochemical decomposition of TEMPO was observed with prolonged irradiation (Figure 2h). In DMSO, the quantum yield

for the formation of TEMPO increased significantly to 13.1% (from 2a) and 12.8% (from 2b) at ≈1% conversion of 2 under atmospheric conditions (Figure 1). The notable effect of the solvent on the TEMPO generation may be due to the increase in the lifetime of the excited states. Photochemical decomposition of TEMPO in DMSO was found to be faster than that in benzene, but the chemical yield of TEMPO (56% from 2a and 58% from 2b after 40 s irradiation) was found to be lower than that obtained in benzene (Figure 1).

The TP photolysis of 2a (10 mM) and 2b (10 mM) was carried out in benzene under atmospheric conditions using 710, 720, 730, 740, 750, and 760 nm near infrared light from a Ti:sapphire laser (pulse width 100 fs, 80 MHz) emitting at an average of 700 mW (Figure 3 for 2a and Supporting Information File 1, Figure S6 for 2b). The typical EPR signals of TEMPO were also observed after TP excitation of 2a and 2b (Supporting Information File 1, Figure S7). The formation of TEMPO at 740 nm, \( k_{740} = 4.9 \times 10^{-6} \text{ s}^{-1} \) in the bulk photoreaction, was the fastest in the TP-uncaging reaction of 2a (Figure 3). For the uncaging reaction of 2b, the rate of consumption under 730 nm irradiation, \( k_{730} = 1.6 \times 10^{-6} \text{ s}^{-1} \), was larger than those at other wavelengths (Supporting Information File 1, Figure S6).
720 nm [58]. The TP cross-section of 2a was higher than that of 2b by ≈15 GM. This higher GM value may be due to the stronger donor–acceptor character of 2a relative to that of 2b, because the electron-donating alkyl group is located at the para-position of the p-nitrophenyl group in 2a.

As observed in the OP uncaging reaction at 365 nm, the efficiency of the TP-induced TEMPO uncaging reaction of 2a was almost three times higher than that of 2b in benzene. This is attributed to the substituent effect of the meta-alkoxy group on the reactivity in the electronically excited states [70]. Moreover, the relative stability of radicals BRa and BRb generated by the photolysis of 2a and 2b had an important impact on the uncaging efficiency. The isodesmic reaction shown in Scheme 4 suggests the radical BRa derived from 2a was 2.04 kcal mol\(^{-1}\) more stable than BRb generated from 2b based on DFT calculations at the B3LYP/6-31G(d) level of theory. In DMSO, no significant difference between 2a and 2b was observed for the photochemical release of the TEMPO species, although the solvent effect is not clearly explained.

As mentioned above, the spatiotemporally controlled generation of the radical pair of TEMPO and BR was confirmed in the photolysis of compounds 2a and 2b. Because free radicals play important roles as anticancer therapeutic agents, the cytocidal effect of the radical released from compound 2a was also tested in vitro using lung cancer cells. One hundred thousand Lewis lung carcinoma (LLC) cells were seeded into 24-well plates (medium: DMEM) and incubated overnight at 37 °C under an atmosphere of 95% air and 5% CO\(_2\). The medium was replaced with fresh phenol-red free DMEM containing various concentrations of 2a (0, 10, 100 μg mL\(^{-1}\)) and further incubated for 4 h under the same conditions. Without exposure to light, 2a itself exhibited slight cytotoxicity based on trypan blue exclusion, and ≈80–90% living cells remained in the medium containing 100 μg mL\(^{-1}\) of 2a (Supporting Information File 1, Figure S8).

The cytocidal effect of the radicals released from compound 2a on LLC cells was also tested. Four hours after 1 min exposure to 360 nm light in various concentrations of 2a-containing medium, the number of living cells decreased in a 2a concentration-dependent manner (Supporting Information File 1, Figure S9). After exposure of the cells in the medium containing 100 μg mL\(^{-1}\) of 2a, the number of living cells decreased significantly compared to that without exposure (66.5% vs 87.8%, Supporting Information File 1, Figure S10). An irradiation-time-dependent decline in the viability of the LLC cells was also observed (Figure 5). To evaluate whether the cytocidal effect was due to photochemical radical generation, cells exposed to 360 nm light for 1 min and the unexposed congeners were stained by using a ROS-ID oxidative stress detection kit (Enzo Life Sciences, Farmingdale, NY, U.S.A.). Reactive oxygen species (ROS) were detected in the cells irradiated in the 2a-containing medium, but not in the non-irradiated cells in
Figure 5: Irradiation time-dependent decline in viability of LLC cells with compound 2a.

Figure 6: Detection of intracellular ROS only in irradiated LLC cells with 2a-containing medium.

2a-containing medium or the irradiated cells without 2a-containing medium (Figure 6). Thus, the preliminary analyses indicated that the photochemical generation of radicals from 2a induced cancer cell death in vitro, although no in vivo study was performed because of the low water solubility of 2a. At this point, we cannot rule out generation of ROS by photosensitization of the chromophore in the presence of O2 for the cytotoxicity.

Conclusion
In the present study, novel caged nitroxides 2a and 2b having a TP-responsive chromophore were synthesized, and OP- and TP-induced generation of the TEMPO radical with these species was examined. The quantum yields for generation of the TEMPO radical from 2a and 2b were determined to be 2.5% and 0.8% in benzene, respectively. The quantum yields in DMSO were found to be higher than those in benzene, 13.1% and 12.8%, respectively. The OP-uncaging efficiency ($\epsilon \times \Phi$) was found to be 480 and 175 for 2a and 2b, respectively, at 360 ± 10 nm, in benzene, and 3026 and 2995 in DMSO, respectively. The TP efficiency of the TEMPO uncaging reaction was found to be 1.1 GM at 740 nm for 2a and 0.22 GM at 730 nm for 2b in benzene. The TP-induced clean release of the TEMPO radical is expected to be applicable to further physiological studies and site-selective polymerization reactions.

Experimental
All reagents were purchased from commercial sources and were used without additional purification, unless otherwise mentioned. Caged nitroxides 2a and 2b were prepared according to the methods described previously (Scheme 2) and were isolated by silica gel column chromatography and GPC. $^1$H and $^{13}$C NMR spectra were reported in parts per million ($\delta$) by using CDCl$_3$. IR spectra were recorded with a FTIR spectrometer. UV–vis spectra were taken by a SHIMADZU UV-3600 Plus spectrophotometer. Mass spectra were measured by a Mass Spectrometric Thermo Fisher Scientific LTQ Orbitrap XL, performed by the Natural Science Center for Basic Research and Development (N-BARD), Hiroshima University.

Preparation of caged compounds 2a and 2b
6-Ethyl-2-(4-nitropheno)benzofuran (5a). 4-Nitro-1-iodobenzene (16.3 g, 65.5 mmol), Pd(dppf)Cl$_2$ (0.97 g, 1.3 mmol), PPh$_3$ (recrystallized, 0.51 g, 1.9 mmol) and CuI (0.25 g, 1.3 mmol) were added under N$_2$ atmosphere followed by toluene (97 mL) and iPr$_2$NH (49 mL, 359 mmol). The mixture was stirred for 10 min, and TMSA (11.5 mL, 81.6 mmol) was added at room temperature. It was stirred until all iodobenzene was consumed (20 min). TBAF 1 M in THF (100 mL, 100 mmol) was added followed by 5-ethyl-2iodophenol (21.6 g, 86.9 mmol). The temperature was increased to 80 °C, and the mixture was stirred for 21.5 h. The reaction was quenched with 10% aqueous citric acid (400 mL)
and extracted with DCM. The combined extracts were washed with 10% aqueous NaOH (400 mL), water and dried with anhydrous MgSO₄. The solvent was removed by rotary evaporation and the crude product was purified by silica gel column chromatography (hexane/EtOAc 10:1, v/v) to give 6-ethyl-2-(4-nitrophenyl)benzofuran (5a, 10.0 g, 57.3%). mp 114 °C; IR (KBr, cm⁻¹): 3429, 2968, 1601, 1520, 1344, 1108, 828, 825, 754, 692; ¹H NMR (400 MHz, CDCl₃) δ (ppm) 8.30 (d, J = 9.0 Hz, 2H), 7.98 (d, J = 9.0 Hz, 2H), 7.54 (d, J = 8.0 Hz, 1H), 7.39 (s, 1H), 7.20 (d, J = 0.9 Hz, 1H), 7.14 (dd, J = 8.0, 1.4 Hz, 1H), 2.80 (q, J = 7.6 Hz, 2H), 1.32 (t, J = 7.6 Hz, 3H); ¹³C NMR (100 MHz, CDCl₃) δ (ppm) 156.05 (C), 152.86 (C), 147.12 (C), 143.06 (C), 136.56 (C), 126.43 (C), 125.01 (CH), 124.33 (CH), 124.07 (CH), 121.22 (CH), 110.42 (CH), 105.12 (CH), 29.25 (CH₂), 15.84 (CH₃); HRMS–ESI (m/z): [M + H⁺] calcd. for C₁₆H₁₃NO₃, 267.09009; found, 267.09064.

2,2,6,6-Tetramethyl-1-(1-(2-(4-nitrophenyl)benzofuran-6-y1)ethoxy)pyperidine (2a). Under air, TEMPO (0.23 g, 1.5 mmol), 6-ethyl-2-(4-nitrophenyl)benzofuran (5a, 1.26 g, 4.72 mmol), Cu(OAc)₂ (16.5 mg, 0.092 mmol), bpy (13.8 mg, 0.094 mmol), TBHP (aqueous 70%, 0.4 mL, 2.9 mmol) were added into a two-necked flask in the dark. The reaction was stirred at 60 °C for 15 h. Upon completion, the mixture was purified by silica gel column chromatography (hexane/ether 15:1, v/v) to give 2a (236 mg, 37.8%). mp 109 °C; IR (KBr, cm⁻¹): 3429, 2934, 1600, 1521, 1345, 1062, 825; ¹H NMR (400 MHz, CDCl₃) δ (ppm) 8.31 (d, J = 9.0 Hz, 2H), 7.99 (d, J = 9.0 Hz, 2H), 7.57 (d, J = 8.1 Hz, 1H), 7.54 (s, 1H), 7.25 (dd, J = 8.1, 1.2 Hz, 1H), 7.21 (d, J = 0.7 Hz, 1H), 4.91 (q, J = 6.7 Hz, 1H), 1.54 (d, J = 6.6 Hz, 3H), 1.51 (s, 3H), 1.32 (s, 6H), 1.20 (s, 3H), 1.05 (s, 3H), 0.66 (s, 3H); ¹³C NMR (100 MHz, CDCl₃) δ (ppm) 155.69 (C), 153.25 (C), 147.18 (C), 144.70 (C), 136.50 (C), 127.39 (C), 125.08 (CH₃), 124.33 (CH₂), 122.65 (CH), 121.04 (CH), 109.47 (CH), 105.13 (CH), 83.28 (CH), 59.79 (C), 40.43 (CH₂), 34.23 (CH₃), 23.82 (CH₃), 20.40 (CH₃), 17.24 (CH₃); HRMS–ESI (m/z): [M + H⁺] calcd. for C₂₅H₂₃N₂O₄, 423.22783; found, 423.22754.

5-Ethyl-2-(4-nitrophenyl)benzofuran (5b). 4-Nitro-1-iodobenzene (16.8 g, 67.5 mmol), Pd(dppf)Cl₂ (1.0 g, 1.3 mmol), PPH₃ (recrystallized, 0.53 g, 2.0 mmol) and Cul (0.26 g, 1.3 mmol) were added under N₂ atmosphere followed by toluene (100 mL) and iPr₂NH (50.5 mL, 370 mmol). The mixture was stirred for 10 min, and TMSA (1.75 mL, 12.5 mmol) in toluene (10 mL) was added at room temperature. It was stirred until all iodobenzene was consumed (20 min). TBAF 1 M in THF (100 mL, 100 mmol) was added followed by 4-ethyl-2-iodophenol (22.2 g, 89.6 mmol). The temperature was increased to 80 °C, and the mixture was stirred for 20 h. The reaction was quenched with 10% aqueous citric acid (666 mL) and extracted with DCM. Combined extracts were washed with 10% aqueous NaOH (666 mL), water and dried with anhydrous MgSO₄. The solvent was removed by rotary evaporation and the crude product was purified by silica gel column chromatography (hexane/EtOAc 10:1, v/v) to give 5-ethyl-2-(4-nitrophenyl)benzofuran (5b, 12.2 g, 67.6%). mp 129 °C; IR (KBr, cm⁻¹): 2922, 1601, 1514, 1304, 1194, 853, 811, 754, 690; ¹H NMR (400 MHz, CDCl₃) δ (ppm) 8.30 (d, J = 9.0 Hz, 2H), 7.99 (d, J = 9.0 Hz, 2H), 7.46 (d, J = 9.2 Hz, 1H), 7.44 (s, 1H), 7.21 (dd, J = 8.4, 1.8 Hz, 1H), 7.19 (d, J = 0.8 Hz, 1H), 2.76 (q, J = 7.6 Hz, 2H), 1.30 (t, J = 7.6 Hz, 3H); ¹³C NMR (100 MHz, CDCl₃) δ (ppm) 154.12 (C), 153.38 (C), 147.21 (C), 139.74 (C), 136.47 (C), 128.79 (C), 126.24 (CH), 125.12 (CH), 124.29 (CH), 121.14 (CH), 111.12 (CH), 105.04 (CH), 28.83 (CH₃), 16.15 (CH₃); HRMS–ESI (m/z): [M + H⁺] calcd. for C₁₆H₁₃NO₃, 267.09009; found, 267.09030.

Photoirradiation of LLC cells with compound 2a
One hundred thousand Lewis lung carcinoma (LLC) cells were seeded into a 24-well plate (medium: DMEM) and incubated overnight at 37 °C in an atmosphere of 95% air and 5% CO2. The medium was replaced with fresh phenol-red free DMEM containing 100 μg/mL of compound 2a. Four hours after various irradiation time of 360 nm light (0, 10, 30, 60, 90, 120, and 150 s) using a fluorescence microscope (BIOREVO BZ-9000, Keyence, Osaka, Japan), cell viability was determined by trypan blue exclusion. Bars represent the mean ± standard deviation (n = 4).

Detection of intracellular ROS in irradiated LLC cells with 2a-containing medium
Fifty thousand Lewis lung carcinoma (LLC) cells were seeded into 24-well plate (medium: DMEM) and incubated overnight at 37 °C in an atmosphere of 95% air and 5% CO2. The medium was replaced with fresh phenol-red free DMEM containing 0 or 100 μg/mL of compound 2a. Thirty minutes after 1 min or no exposure of 360 nm light using a fluorescence microscope (BIOREVO BZ-9000, Keyence, Osaka, Japan), intracellular ROS were detected using the ROS-ID Oxidative Stress Detection Kit (Enzo Life Sciences, Farmingdale, NY, USA) in conjunction with fluorescence microscopy. Intracellular ROS was detected in the form of green fluorescence signals. Bars, 100 μm.

Vicinal difunctionalization of alkenes by four-component radical cascade reaction of xanthogenates, alkenes, CO, and sulfonyl oxime ethers

Shuhei Sumino1, Takahide Fukuyama1, Mika Sasano1, Ilhyong Ryu*1,2, Antoine Jacquet3, Frédéric Robert3 and Yannick Landais*3

Abstract
Four-component coupling reactions between xanthogenates, alkenes, CO, and sulfonyl oxime ethers were studied. In the presence of hexabutylditin, working as a propagating radical reagent, the chain reaction proceeds, as expected, taking into account reagents polarities, affording the corresponding functionalized α-keto oximes. Although yields are modest, this rare one-pot four-component process is easy to carry out and the resulting compounds, bearing multiple functionalities, have the potential for further elaboration.

Introduction
Multicomponent reactions constitute a powerful and highly efficient tool in organic synthesis to build up intricate compounds from simple molecules in a single operation [1-5]. Needless to say, the contribution by radical chemistry is not trivial [5-7]. While alkenes and alkynes have served as efficient radical donor/acceptor type C2 synthons in multicomponent radical reactions, CO and isonitriles were shown to react as donor/acceptor type C1 synthons [6-15]. In this context, sulfonyl oxime ethers are powerful acceptors of type C1 synthon [8,16,17], which terminates the multicomponent reaction by a β-scission of RSO2 radicals [18-20]. Recently, one of us reported on a three-component radical reaction using xanthogenates, alkenes, and sulfonyl oxime ethers (Scheme 1, reaction 1) [21,22]. The reaction proceeds efficiently to provide good yields of α-alkoxyimino esters, potential precursors of lactams, lactones and β-keto esters. Since the three-component
radical reaction involving alkyl halides and two radical C1 synthons, CO and sulfonyl oxime ethers, is known to be feasible [23–25], we were tempted to explore a novel class of four-component radical reaction [26–28] incorporating a xanthogenate, an alkene, CO, and a sulfonyl oxime ether (Scheme 1, reaction 2). This paper reports on the synthesis of functionalized α-keto oximes through such a one-pot, four-component procedure.

Results and Discussion

We first investigated the reaction of xanthate 1a [29], 1-octene (2a), CO, and sulfonyl oxime ether 3a as a model reaction. When the mixture of 1a, 2a (5 equiv), and 3a (1.2 equiv) in C6H6 (16 mL) in the presence of hexabutylditin as a radical mediator, and DTBHN (di-tert-butyl hyponitrite) as a radical initiator was heated under CO (130 atm) at 45 °C for 16 h, the envisaged four-component coupling product, keto oxime 5a, was obtained in 43% yield, along with the three-component product 4a (4a/5a = 9:91) (Table 1, entry 1). In this reaction, several unidentified byproducts were also formed. Since the conversion of 1a (ca. 70%) was incomplete, a higher concentration ([1a] = 0.05 M) using 8 mL of C6H6 was employed, resulting in a higher conversion (ca. 80%), affording 5a in 47% yield (Table 1, entry 2). The use of DCE (1,2-dichloroethane) as a solvent gave a 50% yield of 5a (Table 1, entry 3). The present four-component product also proceeded under

\(^a\) Reaction conditions: 1a (0.4 mmol), 2a (2 or 4 mmol), CO (130 atm), 3a (0.48 or 0.6 mmol), DTBHN (0.12 mmol), (Bu3Sn)2 (0.8 mmol), C6H6 or DCE (8 mL), 45 °C, 16 h. \(^b\) Determined by GC. \(^c\) GC yields determined by using nonane as an internal standard. Isolated yields by silica gel chromatography are given in the parenthesis. \(^d\) C6H6 (16 mL). Conversion of 1a = ca. 70%. \(^e\) Irradiation by Xe lamp was carried out in the absence of DTBHN.
photoirradiation conditions in the absence of costly DTBHN (Table 1, entry 4). The reaction with 10 equivalents of 2a together with 1.5 equivalents of 3a led to a higher conversion (ca. 90%), affording acceptable yield and selectivity (Table 1, entry 5).

With optimized reaction conditions in hand (Table 1, entry 5), we then examined the generality of this four-component radical cascade reaction using xanthates 1, olefins 2, CO, and oxime esters 3, leading to 5a–l (Figure 1). The xanthate 1b, bearing a phenyl ester, gave similarly to 1a, α-keto oxime 5b in moderate yield. The reaction of 1a or 1b with vinylcyclohexane (2b) in the presence of CO and 3a afforded the corresponding α-keto oximes 5c and 5d in 54 or 32% yield, respectively. The conditions were shown to be compatible with the presence of nitriles, ethers and halogens. Alkenes having a tert-butylidimethylsilyl ether such as 6-siloxy-1-hexene 2c thus participated to the reaction to give 5e in 57% yield. Alkenes having a chlorine atom, as in 2d, were also competent substrates in the present four-component coupling reaction, affording 5f, albeit in modest yield. The reaction of 1a with 6-heptenenitrile (2e) and 5-hexen-2-one (2f) gave the corresponding four-component coupling products 5g and 5h, in 34 and 41% yield, respectively. The reaction with cyano-substituted sulfonyl oxime ester 3b also worked well to provide cyano-functionalized α-keto oximes. 5i, 5j, and 5k were thus accessible through the four-component coupling reaction between xanthogenates, alkenes, CO, and 3b in acceptable isolated yields (39–50%). Finally, the reaction between acetophenone xanthate 1c, 2b and 3a gave the corresponding keto oxime 5l in 39% yield. The functionalized α-keto oximes obtained herein should be useful scaffolds for further functionalization. Indeed, the α-keto oximes were reported to be used for the synthesis of a variety of synthetic intermediates, including functionalized keto-aldehydes [22], aminoalcohols [30], triazoles [31], just to name a few.

A reaction mechanism is finally proposed for the four-component cascade reaction, which is depicted in Figure 2 [22,24,32-34]. Initially, α-carbonyl radical A [8] was generated by the electrophilic

**Figure 1**: Vicinal difunctionalization of alkenes by four-component radical cascade reaction using xanthogenate 1, alkenes 2, CO, and sulfonoyl oxime ethers 3 leading to 5a–l. Reaction conditions: 1 (0.4 mmol), 2 (4 mmol), CO (130 atm), 3 (0.5 mmol), DTBHN (30 mol %), (Bu_3Sn)_2 (0.8 mmol), DCE (8 mL), 45 °C, 16 h.
Figure 2: Proposed radical chain mechanism.

α-carbonyl radical A does not react with CO even at high CO pressure [6], and therefore selectively adds to electron-rich olefin 2a to form a carbon-centered radical B. The radical B, regarded as a nucleophilic radical, then undergoes radical carbonylation with CO to give an acyl radical C [35], which then adds to electron-deficient sulfonyl oxime ether 3a to afford 5a. The resulting radical D then undergoes β-fragmentation providing 5a along with the phenylsulfonyl radical E. S$_3$2 reaction between radical E and hexabutylditin regenerates the tributyltin radical which sustains the radical chain. Since radical B can also add to sulfonyl oxime ether 3a, we used high CO pressure conditions to encourage the radical carbonylation to form acyl radical C.

Conclusion
In summary, we demonstrated that a four-component radical cascade reaction, between xanthogenates, alkenes, CO, and sulfonyl oxime ethers, can proceed under radical mediated conditions, using hexabutylditin as a radical chain carrier, to give the corresponding keto-oximes in moderate yields. A variety of functional groups are tolerated under the high CO pressure and temperature conditions. Among multicomponent reactions, specific four-component reactions are still rare [26-28]. The present procedure, which is easy to carry out using an autoclave in a single operation, shows that a fine tuning of the reaction conditions (pressure and temperature) and reagents polarities offer a straightforward access to polyfunctionalized substrates from readily available starting materials.

Experimental
General information
$^1$H NMR spectra were recorded on a JEOL ECP-500 (500 MHz) and JEOL ECS-400 (400 MHz) spectrometers in CDCl$_3$ and referenced at 0.00 ppm for TMS. $^{13}$C NMR spectra were recorded on a JEOL ECP-500 (125 MHz) and JEOL ECS-400 (100 MHz) spectrometers in CDCl$_3$ and referenced at 77.00 ppm for CHCl$_3$. Chemical shifts are reported in parts per million (δ). Splitting patterns are indicated as follows: br, broad; s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Infrared spectra were obtained on a JASCO FT/IR-4100 spectrometer; absorptions were reported in reciprocal centimeters. High-resolution mass spectra were recorded on a JEOL MS700 spectrometer or Exactive Plus EMR (Thermo Fisher Scientific). The products were purified by flash chromatography on silica gel (Kanto Chem. Co. Silica Gel 60N (spherical, neutral, 40–50 μm)) and, if necessary, were further purified by recycling preparative HPLC (Japan Analytical Industry Co. Ltd., LC-918) equipped with GPC columns (JAIGEL-1H + JAIGEL-2H columns) using CHCl$_3$ as eluent. Xanthogenate 1a,b [20], 1c [36], alkene 2c [37], and oxime ester 3a,b [20] were pre-
pared according to reported procedures. Photoirradiation was carried out using a 500 W Xenon short arc lamp (Usio Co. Ltd., lamp house: SX-U1500XQ, Xenon short arc lamp: UXL-500SX, power supply: BA-X500).

**Typical procedure for the synthesis of 5a under thermal conditions**

A magnetic stirring bar, 1a (90.1 mg, 0.4 mmol), 2a (455.3 mg, 4.0 mmol), 3a (141.4 mg, 0.51 mmol), (Bu$_3$Sn)$_2$ (474.7 mg, 0.82 mmol), DTBHN (21.4 mg, 0.12 mmol), and 1,2-dichloroethane (8 mL) were placed in a stainless steel autoclave. The autoclave was closed, purged three times with carbon monoxide, pressurized with 130 atm of CO and then stirred at 45 °C for 16 h. Excess CO was discharged at room temperature after the reaction. The reaction mixture was then filtered and concentrated in vacuo to give a residue, which was subjected to silica gel column chromatography using hexane/EtOAc 10:1 as eluent, affording 5a (83.7 mg, 0.22 mmol, 52%).

**Procedure for the synthesis of 5a under photoirradiation conditions**

A magnetic stirring bar, 1a (82.0 mg, 0.39 mmol), 2a (225.8 mg, 2.0 mmol), 3a (133.1 mg, 0.48 mmol), (Bu$_3$Sn)$_2$ (452.6 mg, 0.78 mmol), and 1,2-dichloroethane (8 mL) were placed in a stainless steel autoclave. The autoclave was closed, purged three times with carbon monoxide, pressurized with 130 atm of CO and then irradiated by Xenon lamp (500 W) with stirring for 16 h. Excess CO was discharged after the reaction. The reaction mixture was then filtered and concentrated in vacuo to give a residue, which was subjected to silica gel column chromatography using hexane/EtOAc 10:1 as eluent, affording 5a (52.9 mg, 0.15 mmol, 38%).
